Desperately Seeking Superstrings?
by Paul Ginsparg and Sheldon Glashow
Physics Today, May 1986

Why is the smart money all tied up in strings? Why is so much theoretical capital expended upon the properties of supersymmetric systems of quantum strings propagating in ten-dimensional space-time? The good news is that superstring theory may have the right stuff to explain the “low-energy phenomena” of high-energy physics and gravity as well. In the context of possible quantum theories of gravity, each of the few currently known superstring theories may even be unique, finite and self-consistent. In principle a superstring theory ordains what particles exist and what properties they have, using no arbitrary or adjustable parameters. The bad news is that years of intense effort by dozens of the best and the brightest have yielded not one verifiable prediction, nor should any soon be expected. Called “the new physics” by its promoters, it is not even known to encompass the old and established standard model.

In lieu of the traditional confrontation between theory and experiment, superstring theorists pursue an inner harmony where elegance, uniqueness and beauty define truth. The theory depends for its existence upon magical coincidences, miraculous cancellations and relations among seemingly unrelated (and possibly undiscovered) fields of mathematics. Are these properties reasons to accept the reality of superstrings? Do mathematics and aesthetics supplant and transcend mere experiment? Will the mundane phenomenological problems that we know as physics simply come out in the wash in some distant tomorrow? Is further experimental endeavor not only difficult and expensive but unnecessary and irrelevant? Contemplation of superstrings may evolve into an activity as remote from conventional particle physics as particle physics is from chemistry, to be conducted at schools of divinity by future equivalents of medieval theologians. For the first time since the Dark Ages, we can see how our noble search may end, with faith replacing science once again. Superstring sentiments eerily recall “arguments from design” for the existence of a supreme being. Was it only in jest that a leading string theorist suggested that “superstrings may prove as successful as God, Who has after all lasted for millennia and is still invoked in some quarters as a Theory of Nature”?

The trouble began with quantum chromodynamics, an integral part of the standard model that underlies the quark structure of nucleons and the nuclear force itself. QCD is not merely a theory but, within a certain context, the theory of the strong force: It offers a complete description of nuclear and particle physics at accessible energies. While most questions are computationally too difficult for QCD to answer fully, it has had many qualitative (and a few quantitative) confirmations. That QCD is almost certainly “correct” suggests and affirms the belief that elegance and uniqueness — in this case, reinforced by

1
experiment — are criteria for truth.

No observed phenomenon disagrees with or demands structure beyond the standard model. No internal contradictions and few loose ends remain, but there are some vexing puzzles: Why is the gauge group what it is, and what provides the mechanism for its breakdown? Why are there three families of fundamental fermions when one would seem to suffice? Aren’t 17 basic particles and 17 tunable parameters too many? What about a quantum theory of gravity? Quantum field theory doesn’t address these questions, and one can understand its greatest past triumphs without necessarily regarding it as fundamental. Field theory is clearly not the end of the story, so something smaller and better is needed: Enter the superstring.

The trouble is that most of superstring physics lies up at the Planck mass — about $10^{19}$ GeV — and it is a long and treacherous road down to where we can see the light of day. A naive comparison of length scales suggests that to calculate the electron mass from superstrings would be a trillion times more difficult than to explain human behavior in terms of atomic physics. Superstring theory, unless it allows an approximation scheme for yielding useful and testable physical information, might be the sort of thing that Wolfgang Pauli would have said is “not even wrong.” It would continue to attract newcomers to the field simply because it is the only obvious alternative to explaining why certain detectors light up like video games near the end of every funding cycle.

In the old days we moved up in energy step by step, seeing smaller and smaller structures. Observations led to theories or models that suggested further experiments. The going is getting rougher; Colliders are inordinately expensive, detectors have grown immense, and interesting collisions are rare. Not even a politically popular “Superstring Detection Initiative” with a catchy name like “String Wars” could get us to energies where superstrings are relevant. We are stuck with a gap of 16 orders of magnitude between theoretical strings and observable particles, unbridgeable by any currently envisioned experiment. Conventional grand unified theories, which also depend on a remote fundamental energy scale (albeit one extrapolated upward from known phenomena rather than downward from abstract principle), retain the grand virtue that, at least in their simplest form, they were predictive enough to be excluded — by our failure to observe proton decay.

How tempting is the top-down approach! How satisfying and economical to explain everything in one bold stroke of our aesthetic, mathematical or intuitive sensibilities, thus displaying the power of positive thinking without requiring tedious experimentation! But a priori arguments have deluded us from ancient Greece on. Without benefit of the experimental provokedness that led to Maxwell’s equations and, inevitably, to the special theory of relativity, great philosophers pondering for millennia failed even to suspect the basic kinematical structure of space-time. Pure thought could not anticipate the quantum. And even had Albert Einstein succeeded in the quest that consumed the latter half of his
life, somehow finding a framework for unifying electromagnetism and gravity, we would by now have discarded his theory in the light of experimental data to which he had no access. He had to fail, simply because he didn’t know enough physics. Today we can’t exclude the possibility that micro-unicorns might be thriving at a length scale of $10^{-18}$ cm. Einstein’s path, the search for unification now, is likely to remain fruitless.

Having a potentially plausible candidate “theory of everything” does dramatically alter the situation. But we who are haunted by the lingering suspicion that superstrings, despite all the hoopla, may be correct are likely to remain haunted for the foreseeable future. Only a continued influx of experimental ideas and data can allow the paths from top and bottom to meet. The theory of everything may come in its time, but not until we are certain that Nature has exhausted her bag of performable tricks.
